Dependence of the poor on biodiversity: which poor, what biodiversity?

Bhaskar Vira and Andreas Kontoleon

June 2010

Paper prepared for the CPRC International Conference 2010,
Manchester, September 8-10, 2010.

ABSTRACT

This paper examines the evidence on the extent to which the poor depend upon biodiversity. It specifically focuses on the question: which groups of the (differentiated) poor depend, in which types of ways, on different elements of biological diversity? The review focused on two particular types of dependence: (a) biodiversity as offering a means of subsistence or income to the poor; and (b) biodiversity as offering insurance to the poor from risks and shocks which prevents them from falling deeper into poverty.

The methodology for the review included an examination of the peer-reviewed literature, as published in journals and books, and an examination of websites and portals of major organisations/forums working on biodiversity conservation and poverty alleviation. Literature identified through these processes was systematically analysed to examine the empirical evidence on the extent and nature of dependence. Aggregation of the findings from this meta-analysis is difficult, given the methodological differences in the underlying case studies, but this paper reports on the trends that have emerged from this review.

There is considerable variation reported in the extent of household income that is contributed by biodiversity-based resources. Some of this dependence is very specific to particular groups, especially the poor. Some multi-sited studies demonstrate variability across different sites, reflecting both the availability of alternative income sources, as well as access issues and previous resource use patterns. Levels of participation in biodiversity based livelihood activities are also high, although there is some variation when this is broken down by wealth class, with the poor typically showing higher levels of dependence.

The literature suggests that biodiversity provides the poor a form of cost effective and readily accessible insurance against risk, particularly food security
risks, risks from environmental hazards, and health risks. There is also some discussion in the reviewed material of the risks associated with declining ecosystem resilience. The evidence suggests that, as the poor have few alternative sources for protecting themselves, they have a higher dependency on biodiversity for dealing with risk.

The reviewed studies suggest that the poor tend to depend disproportionately on relatively low value or ‘inferior’ goods and services from biodiversity, while the more affluent groups may get interested in such resources if they have higher commercial values (often crowding out the poor in the process). Similarly, risk dependence of the poor on biodiversity takes the form of a last resort, in the absence of alternatives. This dependence of the poor on low value activities (and on biodiversity as a last resort against various forms of risk) may confirm the suggestion in some recent literature of a resource-based ‘poverty trap’. This may have important policy implications, as it suggests that the poor may need to break their dependence on biodiversity in order to improve their livelihood outcomes.

1. INTRODUCTION

The poverty-environment relationship has been conceptualised in a variety of ways since first coming to attention during the 1970s. Understanding has evolved from relatively simplistic demographically-deterministic models which suggested an inevitable downward spiral, to a recognition of the institutional and structural contexts which result in these negative feedbacks, and an understanding of the wider political economy factors which shape resource use practices and environmental exploitation (Duraiappah 1998). Subsequently, studies have documented the importance of environmental resources for the livelihoods and incomes of poor people, suggesting that the impact of natural resource degradation was particularly felt by the poorest communities (Broad 1994, Scherr 2000, Nadkarni 2000). These studies demonstrated empirically that the poorest groups tended to derive a greater proportion of their household income and livelihood needs from the natural resource base, hence were disproportionately dependent on these resources.

More recently, attention has turned to attempts to understand the relationship between biological diversity and poverty, specifically in response to the growing convergence of these agendas within the international policy context (Adams et al 2004, Roe and Elliot 2005). Recognising these linkages, the United Nations Convention on Biological Diversity (CBD) adopted a decision in 2002 “to achieve by 2010 a significant reduction of the current rate of biodiversity loss at the global, regional and national level as a contribution to poverty alleviation and to the benefit of all life on earth.” While the headline commitment to reducing biodiversity loss is unlikely to be met this year, the attention to the relation with global poverty alleviation targets has meant that these twin issues have been the focus of attention for global and national policy makers over the last decade.

Although these links between the biodiversity conservation and poverty alleviation agendas have been widely accepted, the specific nature of the
relationship between biodiversity and poverty is still not well understood. At their broadest level, two types of links can be identified: (i) biodiversity as a means of subsistence or income, providing inputs into poor peoples' livelihoods: (ii) biodiversity as insurance, providing a buffer against risks and shocks, helping smooth livelihoods and consumption patterns. While these relationships have been empirically documented in a wide variety of circumstances, there is still a considerable need to investigate these linkages more critically, and with greater analytical clarity. Crucially, recognising that both biodiversity and poverty can manifest themselves in different guises, it is important to interrogate a more nuanced question: which groups of the (differentiated) poor depend, in which types of ways, on different elements of biological diversity?

This paper represents a first attempt to address this question. It is based on a systematic review of literature on the ways in which poor people depend on biodiversity as a direct contribution to their subsistence, income and other livelihood needs, and as a source of risk coping and insurance. It examines the published literature, in order to document broad trends emerging from existing knowledge about these relationships, and to identify key areas where there are knowledge gaps.

In the next section we address some fundamental conceptual issues which relate to the ways in which the terms ‘biodiversity’ and ‘poverty’ are used and understood. Section 3 describes the methodology used for the review. Sections 4 and 5 are the empirical core of the paper, discussing in detail the findings from the review about the extent to which aspects of biodiversity link with specific livelihood and insurance needs for people, especially the poor. Section 6 concludes.

2. DEFINITIONAL ISSUES

2.1 BIODIVERSITY

Biodiversity is widely understood to refer to three dimensions within which variability occurs: genetic, meaning the variation of genes within a species, subspecies or population; population/species, meaning the variation between living species and their component populations at different spatial scales (local, regional or global); and community/ecosystem, meaning the variation within ecological complexes of which species are a part.

Defined in this way, relatively few of the detailed micro studies that were reviewed in this paper explicitly focused on ‘biodiversity’. The term ‘nature’s resources’ better captures the generic categories of resources that have been studied in this literature. These include forests, both in terms of wood-based and non-timber forest products (NTFPs) (forming a clear majority, together 18 out of 27 detailed cases); mangroves; fish; wild animals (bushmeat) and wild plants (including herbs); and common pool resources (CPRs) more generally.

Keeping this in mind, we need to be cautious about how we interpret the material that has been the subject of this review. While nature’s resources are
clearly very central to the livelihood strategies of the poor, we cannot make the assumption that these activities require or depend upon the existence of biodiversity. Indeed, lack of diversity may not harm certain types of uses (such as the harvesting of particular NTFPs), as long as the specific resource that is being exploited remains relatively abundant. Monoculture plantations of the most valuable species may provide sustainable inputs into household livelihoods, but may not be related to biological diversity in any recognisable sense.

Moreover, as several studies document, wild plants that are in increasing demand (for instance, for medicinal purposes) are frequently being domesticated for cultivation as their values increase, bringing their use patterns closer to those of farming systems (and thereby breaking the link with ‘biodiverse nature’). The dependence of poor (and rich) rural populations on these species for their livelihoods does not necessarily change, but they are being managed in conditions that are very different to their origins in the wild. This raises important challenges to the ways in which we conceptualise these use patterns, although these distinctions (between ‘wild’ and ‘farmed’) may in some cases be less meaningful to the actual communities who are actually engaged in the management and exploitation of these species.

The different components of biodiversity (genetic, species and ecosystem) are not necessarily equally important in order to maintain the flows of resources on which the livelihoods of the poor depend. The literature on resource dependence does not trace the links between these components, the resources that emerge from nature, and the livelihoods of the poor. In terms of contributions to livelihoods, what is often valuable is the volume (in terms of extent and abundance) of a resource, rather than diversity. While an assumption can be made that wild resources, harvested from nature, do depend on the existence of biological diversity in a general sense, there is an urgent need to document more clearly the specific parameters of this relationship. Although the link is often asserted (as for instance, in the Millennium Ecosystem Assessment Conceptual Framework, where Biodiversity (Life on Earth) underpins all ecosystem services), what is not necessarily clear is the ways in which changes in biodiversity affect the resources that provide inputs into poor people’s livelihoods (Ash and Jenkins 2007).

2.2 POVERTY

It is widely recognised that our understanding of poverty has moved on considerably from its original definitions, which focused on (a lack of) income or wealth. Poverty is now seen as multi-dimensional, encompassing material deprivation, the lack of access to other basic needs (education, health, nutrition and food security), the absence of political autonomy and empowerment, as well as the lack of freedom of choice and social inequality. Moreover, research also differentiates between the occurrence of poverty (its ‘incidence’), its intensity, the extent of inequality (i.e. the distribution of income between rich and poor), its temporality (chronic versus temporary poverty), and its spatiality. Mainstream poverty research is becoming more sophisticated in its handling of
some of these issues, both through a diversification of methods (quantitative and qualitative), as well as by more inclusive processes of assessment which increasingly include the perspectives of the poor (see reviews in Addison et al 2009).

In their review of the links between poverty, development and biodiversity conservation, Agrawal and Redford (2006, p.12) propose a useful way of “parsing poverty” in two ways: first, ‘aspects’ of poverty, in terms of incidence, intensity, inequality, temporality and spatiality; and second, ‘dimensions’ of poverty, such as income/wealth, education, health, nutrition, food security, political autonomy, empowerment, and social equality. These two concepts were used to interrogate the detailed case studies that form the focus of this review (see Appendix, Table A1). Unfortunately, the reviewed material does not engage with poverty in its multiple aspects and dimensions, and tends to focus almost exclusively on the incidence of poverty defined in material wealth, or income terms (although the concept is usually expanded to include the values of non-market goods and services derived from nature). Some studies also pay attention to issues of inequality, though this is still measured in terms of income inequality (typically through the use of the Gini coefficient).

In a wide ranging review, Angelsen and Wunder (2003) address the links between poverty and forests, and engage with the emergent, more sophisticated approaches to conceptualising poverty, and their potential implications for our understanding of the livelihoods of forest-dependent people. They suggest that it may be useful to distinguish between the way we ‘think about’ poverty, which can be multi-dimensional and complex, and the way we ‘measure’ it, which needs robust and reliable techniques that lend themselves to replication and comparison. To this extent, measurement may continue to rely on more narrow indicators, such as income, levels of consumption, or composite indices which assess wealth or stocks of assets, but discussion about livelihoods may focus on wider concepts which include both poverty (in this narrow sense), and ‘human well-being’, which can include many of the more difficult to measure concepts that have been highlighted in recent discussions about poverty.

This parsimonious approach appears to be the general rule that has been adopted in the literature that is under review for the current context, which adopts a traditional and narrow approach to the measurement of (income) poverty. What is missing from most of these analyses are several of the more interesting dimensions that have been highlighted in recent poverty research, many of which have potential impacts on the ways in which rural people interact with nature’s resources. For instance, while studies point to the seasonality of resource use, and the importance of natural resources both for meeting consumption and employment/income needs during lean seasons (for instance, de Merode et al 2004; Bene et al 2009), these analyses do not address the volatility of poverty, and the extent to which some rural populations cycle in and out of poverty, while others remain chronically poor. If nature’s resources help to temporally smooth consumption and incomes, their poverty impacts may be better captured through an explicit focus on this temporality as part of our poverty measure, instead of restricting our understanding to annualised income
or consumption (in which these temporary contributions from nature do not always feature as significant). Similarly, trying to incorporate wider issues of empowerment, social exclusion and autonomy may be very important in understanding the context within which particular groups experience material deprivation, and may help frame our understanding of the potential for resource based interventions to offer potential pathways out of poverty. So, for instance, increasing the value of nature based goods and services may result in their capture by politically powerful local actors, thereby excluding the very poor from access to potential benefits. Unless issues of political decision making and social inclusion are tackled at the same time, such resource based interventions may do little to help the resource dependent rural populations who are their intended targets.

3. METHODOLOGY

This paper is based on a careful analysis of the current state of knowledge, especially differentiating between robust evidence and claims that are less well-founded on empirical experience, between differences of opinion in the available literature, between different types of knowledge, as well as the identities of those who have generated this knowledge, and what their agendas/positionalities might be.

The specific steps that were undertaken as part of this process were:

i. An examination of the peer-reviewed literature, as published in journals and books. A number of search terms were used to carry out a web-based search in major electronic databases of journal articles and books (including Web of Science, JSTOR, IngentaConnect, Science Direct, Digital Library of the Commons, CAB Abstracts, OCLC FirstSearch, as well as catalogues from the British Library and US Library of Congress). Access to these was secured using the resources of the Cambridge University Library, including both print and electronic holdings.

ii. An examination of websites and portals of major organisations/forums working on biodiversity conservation and poverty alleviation. Key websites that were examined were: Poverty and Conservation Learning Group; the Equator Initiative; UNEP-WCMC; International Institute for Environment and Development (IIED); Department for International Development (DFID); World Bank; Conservation International; The Nature Conservancy; Worldwide Fund for Nature (WWF); Center for International Forestry Research (CIFOR); and the Millennium Ecosystem Assessment (MEA).

The literature that was identified in these two steps was then further short-listed to focus on studies that provided direct evidence that was relevant to this review. A final set of 200 studies were examined in detail (as listed in the bibliography). From these studies, 27 specifically focused on empirical evidence for the dependence of the poor on biodiversity, and these are discussed in detail in this document (see Appendix Table A2 for details), while a further 22 dealt with evidence on risk coping and insurance.
4. DEPENDENCE ON BIODIVERSITY: DIRECT LIVELIHOOD LINKAGES

This review focused on the question: which groups of the (differentiated) poor depend, in which types of ways, on different elements of biological diversity? As has already been discussed, the extent to which the different case studies provided evidence on these issues varied greatly. Table A2 in the Appendix summarises the evidence from these case studies, which provides the basis for the discussion in this section. Given the variation in the extent to which each study has covered issues such as differences between different income classes in the population, impacts on economic and social inequality, and extent of dependence on identifiable elements of biological diversity, this section will summarise key trends that are emergent from this literature, but will not attempt any overall summary. Furthermore, all meta-analyses suffer from an important limitation, which is that the lack of consistency in case study methods precludes any easy aggregation of results, so this will not be attempted here.

This section provides an overview of the evidence on different types of dependence on biodiversity-based resources, primarily derived from micro studies at specific local sites. Unsubstantiated claims, such as those that are often found in larger macro- or sectoral studies, have not been included here, since the evidence for these claims is not available. What emerges from this review is a complex picture, with site- and resource-specific patterns of access, use and dependence, often reflecting very divergent patterns, although some regularities can also be observed from these studies.

4.1 Evidence on dependence: Most studies document income from biodiversity based resources as a percentage of total household income as an indicator of the extent of dependence. Table 1 summarises the findings from these studies.

</tbody>
</table>
As Table 1 demonstrates, there is considerable variation reported in the extent of household income that is contributed by biodiversity based resources. Some of this dependence is very specific to particular groups (such as the poorest fish-dependent groups in Bene et al 2009, for whom fishing represents 90% of household income). Moreover, some multi-sited studies demonstrate variability across different sites, reflecting both the availability of alternative income sources (such as in the case of Fu et al’s 2009 study of two sites in China), as well as access issues and previous resource use patterns (such as the variation across three proximate sites reported in Shaanker et al 2004).

A number of studies additionally report the proportion of households engaged in particular types of activities, which will be used here as an indicator of the ‘depth’ of dependence on biodiversity resources. These findings are summarised in Table 2.

</tr>
<tr>
<td>Shackleton and Shackleton 2006</td>
<td>Southern Africa</td>
<td>96-100% of households purchase NTFPs</td>
<td>NTFPs</td>
</tr>
</tbody>
</table>
Table 2 shows that the depth of dependence reported in these studies is high, although there is some variation when this is broken down by wealth class, with the poor typically showing higher levels of dependence.

A further set of studies also focus on biodiversity based resources as part of household consumption and production strategies (without monetising these values as a proportion of income). These studies are summarised in Table 3.

### Table 3: Other evidence on dependence on biodiversity resources

<table>
<thead>
<tr>
<th>Source</th>
<th>Region</th>
<th>Type of data</th>
<th>Evidence</th>
<th>Resource type</th>
</tr>
</thead>
<tbody>
<tr>
<td>Bene et al 2009</td>
<td>West Africa</td>
<td>Consumption</td>
<td>Varies from 33% (poorest) – 20% (richest)</td>
<td>Fish</td>
</tr>

<td>de Merode et al 2004</td>
<td>West Africa</td>
<td>Consumption</td>
<td>10% of household consumption</td>
<td>Wild foods</td>
</tr>
<tr>
<td>de Merode et al 2004</td>
<td>West Africa</td>
<td>Production</td>
<td>31% of household production</td>
<td>Wild foods</td>
</tr>
</tbody>
</table>

Overall, this data suggests reasonably high levels of dependence on biodiversity based resources, in terms of contributions to household incomes, as well as production and consumption strategies. Levels of participation in biodiversity based livelihood activities are also high, suggesting that the depth of dependence on these resources is significant.

### 4.2 Relative dependence on biodiversity resources: are the poor disproportionately dependent?

The evidence on the relative dependence of rich and poor groups on biodiversity based resources has been the subject of considerable interest, and is somewhat mixed. An early set of studies seemed to suggest unambiguously that the poor were disproportionately dependent on such resources (e.g. Jodha 1990, and Cavendish 2000). This became accepted wisdom, with overviews of the field consistently suggesting that the poor depend proportionately more on nature for their resource needs (Millennium Assessment 2005). However, more recent work has started to question this accepted view, and the studies reviewed here present a more mixed picture.

One factor that has been highlighted in recent work is the complementarity between asset ownership (especially land and cattle), and the use of certain types of biological resources (see for instance, Adhikari et al 2004, Coomes et al 2004, Coulibaly et al 2009, Fisher 2004 and Narain et al 2008a). In these circumstances, asset rich households tend to depend more on nature’s resources. If this difference in asset ownership is further reflected in greater political power at local level, rich households are also able to use their dominance to secure access to resources, and to exclude the relatively poor.
These differences in political power suggest another reason why resource use may be skewed in favour of the rich. While a biodiversity based resource remains relatively low value, rich users tend not to feel the need to restrict access. However, with returns to certain types of resources increasing as they become more valuable and in greater demand, the rich and powerful groups may try and capture these resources, and may exclude the poor from access (see for instance, Fisher 2004).

Table 4 summarises the evidence of the reviewed studies on the extent to which resource access increases or decreases with increases in household wealth.

</tbody>
</table>
A number of interesting patterns emerge from the data that is presented in Table 4. ‘Inferior’, or low value, goods and services tend to be the ones that reflect the conventional wisdom, in that the poor tend to depend disproportionately more on these resources. On the other hand, where commercial production and sales are involved, or if resources complement existing assets such as land and livestock, this relationship may be reversed. This has important implications for the potential of biodiversity based resources to be used as part of poverty-alleviation strategies, which is the subject of a parallel study. If the rich capture resources once they become more valuable, increasing the value of biodiversity based resources may not be a feasible strategy, since the poor may eventually lose out in such a scenario (Angelsen and Wunder 2003).

A second implication of this material is that there appears to be some confirmation of what Angelsen and Wunder (2003) have referred to as a ‘poverty trap’. The poor appear to be linked with low value nature based resource use, but these low values may serve to perpetuate poverty. Here, poverty is endogenous, in the sense that biodiversity resource dependence is a symptom of poverty, and it is only by ‘leaving the forest’ that the poor can hope to escape poverty (Levang et al 2005). This, of course, is an important issue for discussion, since it has been widely believed that biodiversity based resources provide an essential safety net for the poor, preventing them from destitution. But, if this dependence is reproducing patterns of poverty, it may be important to examine alternative livelihood strategies in order to benefit these economically marginalised groups.

### 4.3 Impacts on inequality: does the inclusion of biodiversity based resources improve distributional outcomes?

If the poor do depend disproportionately on biodiversity based resources for their livelihoods, one outcome that emerges is that the inclusion of such resources in estimates of household income are likely to improve equity (measured in terms of reducing income inequality, or a lower Gini coefficient). A number of studies explicitly focus on this issue, and their findings are reviewed in Table 5, below.

#### Table 5: Equity implications of biodiversity resource dependence

</tbody>
</table>
While the data in Table 5 clearly demonstrates that these studies find improvements in distributional outcomes due to the inclusion of biodiversity dependent livelihood strategies in their analyses, there is reason to be cautious in light of the previous discussion about the dependence of wealthier groups on certain high value resources. Clearly, in these circumstances, distributional outcomes would be worse if we were to include biodiversity resources in our analysis, and a biodiversity based strategy would not necessarily improve equity.

Apart from their focus on measures of income inequality, a couple of studies also looked at other indicators of social inequality. Thus, Adhikari et al (2004) report a lower level of resource dependence amongst both female-headed households, as well as lower social castes. This is explained both due to restrictions on access, as well as the lack of complementary assets such as land and livestock. The influence of caste is also remarked upon by Sapkota and Oden (2008), although they show a greater degree of dependence among lower castes. In their study, Bene et al (2009) report than while only 69% of women sell fish, 98.6% of men do so, thereby suggesting that women are less likely to engage in commercial or market driven development opportunities in this context. Glaser (2003) remarks that ‘pure subsistence products’ are most important for the weakest sections, especially women and children. Levang et al (2005) reflect on the importance of geographical isolation, and suggest that resource dependence is highest in remote areas due to the lack of alternatives (suggesting an interesting spatiality to the issue of biodiversity resource dependence). This is also reflected in Fu et al's (2009) study which shows greater dependence in the less developed (remote) village as compared to the more developed (better connected) village.

### 5. DEPENDENCE ON BIODIVERSITY: INSURANCE AND RISK COPING

This section focuses on reviewing the empirical evidence on the importance (in terms of various measures of impact on human welfare) that specific ‘components’ and/or ‘attributes’ of biodiversity have on the ability that the poor have to deal with risks and shocks. In other words we assess the ‘insurance value’ of biodiversity to the poor based on how biodiversity is defined or conceptualised in each study. The empirical literature on biodiversity as a means for risk coping is considerably smaller than that on biodiversity as a source of livelihood. The bulk of this risk coping literature is related to food security. There are considerably fewer studies on natural hazards and no specific studies on the insurance value of biodiversity with respect to the risk of reduction in ecosystem resilience, or the risk of ill health. Moreover, the methods used to assess ‘dependency’ are more varied than those on biodiversity as a source of livelihood. This makes tabulation of results (as in the previous section) less informative.
The literature discusses three main categories of risks in relation to biodiversity: food security risks (e.g. high variability in crop production); environmental and weather hazards (e.g. storms; floods, mudslides etc), and health risks (e.g. risk from infectious diseases; risk of illness due to lack of wild medicinal herbs etc). A fourth type of risk that is discussed in the biodiversity poverty literature is that of risks that are associated with degrading ecosystem resilience. The latter refers to a stability property of ecosystems that reflects the capacity of a system to absorb shocks (Perrings 1995), or the rate at which a system variable returns to the reference state after perturbation (Schläpfer et al 2002) This is a more complex risk to isolate as it permeates the three other type of risks mentioned above. Low levels of biodiversity are argued to lead to lower levels of resilience which ‘lowers the bar’ of the tipping point for a particular ecosystem; i.e. the threshold point below which the ecosystem is not able of providing the same type, level and quality of ecosystem services as before.

5.1 Agro-biodiversity for food security insurance

There is considerable evidence from the ecology and agronomy literatures on the relationship between agro-biodiversity and crop productivity and variability and yield shocks. There are various complex channels that give rise to these effects. For example, diverse crop species are shown to adapt better to environmental changes since the larger pool of different metabolic traits and metabolic pathways enables them to more effectively use resources (such as water and soil nutrients) over a broad range of environmental conditions. (Schlapfer et al 2002). Also, biodiversity has been shown to improve ecosystem resilience which provides insurance against crop failure due to shocks (Perrings 1995, Tilman and Downing 1994; Tilman 1996b).

At an economic policy level the benefits of agro biodiversity for the poor have been acknowledged within the environment and development literature (e.g. review papers by Heal 2000; Jackson et al 2007; Pascual and Perrings 2007; Perrings 2001; Perrings et al 2006; Perrings 2007; Ravi et al 2006 Smale and Drucker 2008). Further the theoretical economics literature has developed bio-economic models that have clarified and defined in economic terms the insurance benefits or value that agro-biodiversity entails (e.g. Evenson et al 1998, Weitzman 1993; Polasky and Solow 1995; Baumgartner and. Quas 2008, Chavas 2009; Heal et al 2004; Schläpfer et al 2002; Quas and Baumgärtner (2006). These biodiversity benefits are then conjectured to be more important for the poor as they provide a cost effective insurance policy against the risk of food insecurity to segments of the populations that do not have alternative risk coping mechanisms (Heal 2000).

Our review suggests that the empirical evidence documenting the degree and nature of this dependence (i.e. how valuable is this insurance value to the poor) is a dynamic body of work with several notable advancements but with significant shortcomings. The most informative body of work concerns studies that have explored the impact of on farm crop genetic diversity on the production (mean of yields) and variability (variance of yields). This has been accomplished using both regional and plot level data. Variants of stochastic production
function approaches and forms of hedonic analysis have been used. The main dependent variables of these studies are mean and variance of the yield of a specific crop (or family of crops). Only a few studies have focused on assessing variability of income (e.g. Di Falco and Perrings, 2003). The main independent variables are those prescribed by economic theory to be included in the estimation of production functions (e.g. input data as well as other socio-economic variables) plus some measure of agro-biodiversity. Various measures of diversity have been used depending on the nature of the study. The main examples of these studies are: Just and Candler 1985, Smale et al., 1998, 2003, 2008; Widawsky and Rozelle, 1998, Meng et al 2003; Di Falco and Perrings 2005; Di Falco and Chavas 2008b; Heisey et al 1997).

A very strong and consistent finding across all these studies is that the coefficient of on farm crop genetic diversity has a strong positive effect on the mean of crop yields and a negative effect on the variance of crop yields. This implies that on farm agro-biodiversity reduces food risk insecurity, something which is particularly important for the poor. It is important to note that this result is robust against different production function specifications, different types of crops, different scales of data (regional vs. plot specific) and different measures of crop genetic diversity. The policy implication of this body of work is that though environmental changes such as rainfall reductions have adverse effects on agroecosystem productivity, these adverse effects can be buffered in the short term and possibly reversed in the longer term under increased agro-biodiversity. In other words, this body of evidence suggests that agro-biodiversity can buffer and insure the poor against negative environmental effects and support the resilience of the system under adverse weather conditions associated with climate change (Di Falco and Perrings 2008).

A few recent production function studies have expanded upon the work noted above and have also tried to examine the value of biodiversity not only as insurance against yield variability but also against the risks of total crop failure due to exogenous shocks (e.g. storms, new invasive pests etc). The main examples of this are in work by Di Falco and Chavas (2009, 2008a and 2006). Their approach is also based on estimating a stochastic production function but their work does not only assess the impact of genetic diversity on the mean and variance of the production variable but also explores the impact on higher moments of the distribution, namely skewness. An increase in the skewness of yield entails a reduction in downside risk exposure (i.e. a decrease in the probability of crop failure due to shocks). For example in their recent work Di Falco and Chavas (2009) use plot level barely production data from Ethiopia and show that agro-biodiversity (more diverse portfolio of barely landraces) increases farm productivity of barely in Ethiopia farms. Further they show that agro-biodiversity decreases downside risk exposure (by increasing skewness of the crop yield distribution). This effect is shown to dominate other confounding effects so that higher biodiversity tends to reduce the cost of risk (as measured by their estimated risk premiums). Finally, they also find that the risk benefit of biodiversity becomes larger under less fertile soils which offers empirical evidence that biodiversity can aid farmers to cope with harsh climatic conditions, especially in degraded lands. This last finding has implications for
poorer segments of the population that tend to use and occupy less fertile, degraded, and marginal lands.

Beyond the relatively homogenous type of work mentioned above (relying on production function approaches) there are a few other types of empirical studies that shed light on the dependency of the poor on agro-biodiversity for food security insurance. Some studies try to compare more directly the impact of adopting modern crop varieties (often provided by aid agencies) as opposed to using traditional landraces on agricultural production decisions and outcomes. Though modern varieties are developed to be more efficient they do require specific types and quantities of inputs and hence may not be helpful in remote poverty-stricken areas where labour and other inputs are scarce. The rationale in this empirical work is that widespread adoption of modern varieties erodes genetic diversity and this may have implications for coping with food security risk in marginal low productivity lands. For example, Lipper et al (2008) study subsistence level sorghum production in Ethiopia. They show that the likelihood of crop failure due to drought increases as the likelihood of adopting modern crop varieties (over traditional landraces) increases. This effect is found to be worse for marginal low production farms occupied by the poorer segments of the population. This provides further support of the insurance value of traditional landraces (which have a higher degree of genetic diversity as compared to modern varieties). Other form of evidence stems form the literature that assesses the factors that impact decisions to conserve in situ crop and animal diversity (see Van Dusen and Taylor 2005). For example, Van Dusen et al 2007 study decisions to conserve diverse rice landraces in Nepal. They find the decision to conserve a diverse portfolio of rice landraces declines with income and increases with distance to markets. Both effects suggest a dependence of the poor on agro-biodiversity. Similar findings are reported in Mexico (in Van Dusen et al 2000). Lastly, there are a few stated preference studies relying on choice experiment methods. These methods directly elicit farm household preferences for different levels of agro-biodiversity with the aim of calculating the welfare (consumer surplus) associated with conserving on farm genetic diversity (e.g. Birol et al 2009 and 2006). This work shows that landrace conservation has a significant welfare enhancing effect (measured as a change in consumer surplus) on farm households in developing countries.

With respect to role of livestock as insurance for the poor, there is ample discussion and evidence in the development economics and development studies literature that this is significant (e.g. Dercon 1998, Fafchamps et al 1998, Kinsey 1998). Further there is some recent literature discussing the special role of animal genetic resources as a distinct concept from livestock, characterised by the properties of flexibility, resilience and diversity. Such animal genetic resources are argued to provide an enhanced form of insurance, as they are vital assets for the livelihoods of the poor (Anderson, 2003, Wollny 2003). This may be so, but empirical studies detailing the insurance value of having access to diverse animal genetic resources are non-existent. Likewise, the benefits to the poor of landscape level biodiversity as an insurance mechanism against high levels of crop variability (for example via its function as enhancing resilience)
though scientifically plausible and explainable both in ecological and economic terms, has not been explored empirically.

5.2 Wild food products, biodiversity and food security

A substantial amount of the literature reviewed in the first sections of this review examines the dependency of the poor on biodiversity as reflected in the proportion of their income that is derived from forests. The same literature is also useful in providing insights on the dependency of the poor on wild food products in particular for coping with the risk of food security. This is so because these studies also calculate the source or composition of income. For example the Vedeld (2005) meta-analysis study suggests that together with fuel wood, wild food products are the main source of forest related income and consumption. This sort of evidence has lends support to the idea of forests as ‘safety nets’. Yet, (and what concerns this review) the value of the ‘diversity’ of wild food items or the value a diverse ecosystems as providing better qualities and quantities of such wild foods is not well documented.

A few more informative studies assess the role of tropical forests (and hence biodiversity rich ecosystems) as an insurance against food security (and income) variability. The study of Pattanayak and Sills (2001) on the Peruvian rainforest and Takasaki et al. (2002) on the Brazilian Amazon are both based on household level data and suggest that poor households in these tropical areas use the forest to cope with risk ex ante and shocks ex post. In the study by Pattanayak and Sills (2001) the authors found that time spent collecting forest-products was correlated with agricultural yield risks (an income smoothing response) and unforeseen production shocks (a consumption smoothing response). One of the main important findings of the Takasaki et al. (2002) study is that the insurance value of the forest (as a source of wild non-timber forest resources during unforeseen shocks) is much more significant for the poorest segments of their sample. The micro-econometric study by Fisher and Shively (2003) on communities living at the margins of tropical forest of Malawi corroborates and complements the previous findings. They find that rural households rely on tropical forests (for wild foods) for coping with income and consumption shocks and that asset poor households are even more dependent on forests for dealing with such shocks. Similar findings are reported in Akinnifesi et al 2006; World Bank 2007, McSweeney 2003; Sunderlin et al 2000). Hence, at least for the case of poor communities living close to tropical forests, the conjecture that forests act as a safety net against food insecurity seems to be the case.

5.3 Biodiversity and natural hazards

Rural poor communities face serious risk from natural hazards the most common being floods, fires, hurricanes and storms, landslides, dust storms. The lack of market or government insurance of the poor against such hazards has been shown to lead to an exasperation of poverty (Dercon 2006, 2005, 2004, 1996, Dercon and Krishnan 2000, Zimmerman and Carter 2003). Natural ecosystems can play an important role in mitigating these risks as they provide cost-effective insurance. This is achieved through complex inter-relationships
between local geo-morphological traits, weather conditions, as well as soil and land-cover characteristics. Of these, vegetation and soil conditions are more susceptible to human interference (at least at the local level and within the short run). The review by Ash and Jenkins (2007) summarises the links between genetic diversity (be it at the soil, vegetation or landscape level) and mitigating against flood and fire risks. There is less available evidence on the possible links between biodiversity and mitigating against other hazards such as landslides, hurricanes and dust storms.

The risk of flooding is directly related to the water retentive capacity of the soils. This is related to soil and forest land traits. Diversity in soils and forests (e.g. type of plant coverage) is important for regulating water flows though the exact mechanisms are not entirely clear. Still, the literature does seem to conclude that natural forests (which to some degree implies higher levels of biodiversity compared to plantation forests and agricultural landscapes) are associated with higher degrees of flood protection. Higher levels of biodiversity are associated with improved ecosystem capacity to regulate fire patterns, their frequency and their severity. For example, diverse plant species allow vegetation to adapt to fires and reduce wider disturbance of ecosystem integrity. Eroding plant biodiversity and introducing invasive tree species alter fire patterns by reducing their frequency but severely increasing their intensity and extent. Natural resource such as mangroves have been shown to help local communities deal with the risk of hurricanes and storms. Yet, case study evidence linking diversity per se and protection against such harsh climatic events is scant. Both landslides and dust storms are impacted by the extent and nature of vegetation coverage across the relevant ecosystem landscape. With respect to the nature or type of vegetation there is scientific evidence that shows that endemic vegetation outperforms invasive or introduced tree or bush varieties. Yet, links with biodiversity per se seems to be weak or at least not well understood (Ash and Jenkins 2007).

5.4 Biodiversity and health risks

There is a sizable body of research on the links between environmental conditions and health from the medical, epidemiological and social science literatures (see World Bank 2007 for a review). A small subset of this literature tries to investigate the links between biodiversity and health vulnerability (see Daily and Ehrlich 1996, and Chivian and Bernstein, 2008, 2004). Recent literature has identified two main avenues through which biodiversity provides a means for mediating health risk for the poor. The first has to do with the impact that biodiversity has on reducing the risk of infectious diseases. The second has to do with biodiversity as a source of accessible medicinal regiments which are not only curative but are also preventive. The latter feature constitutes biodiversity related medicinal regiments an important means for reducing health risks (Burlingame, 2000; Chivian and Bernstein, 2008, 2004; Frison et a 2005; Grifo and Rosenthal 2007; Huynen et al 2004, Johns 2006; Johns and Eyzaguirre 2006).

a) Biodiversity and risk of infectious disease
There is a growing literature documenting how biodiversity reduces risk of exposure to several types of infectious diseases. Biodiversity at the ecosystem level produces the appropriate balance between predators and prey, hosts, vectors and parasites which allows for appropriate controls and checks for both the spread of ‘endemic’ infectious disease as well as the resistance towards invasive pathogen (from humans, animals or insects). Ash and Jenkins (2007, p. 20) identify a large list of diseases as being particularly dependent on changes in ecosystem biodiversity. Most of these diseases are of particular relevance to the poor and include malaria (in all ecosystem types), schistosomiasis, lymphatic filariasis, and Japanese encephalitis (particularly in cultivated and inland water systems in the tropics), dengue fever (particularly in tropical urban centers), leishmaniasis and Chagas disease (in forest and dryland systems), meningitis (in the Sahel), cholera (in coastal, freshwater, and urban systems), and rabies transmission (in tropics forest lands).

It is evident that regions in the world with the highest levels of poverty are most vulnerable to such diseases. Biodiversity plays a role not only in reducing the risk of such diseases spreading within an ecosystem and the human population living within it but in many cases also reduces the risk of allowing invasive diseases from entering a particular system. For example, there is evidence to show that cholera, kala‐azar, and schistosomiasis have not become established in the (biodiversity rich) Amazonian forest ecosystem despite the risk of this happening from human migration and settlements (Ash and Jenkins 2007).

**b) Biodiversity and preventive wild medicines**

Biodiversity has been recognised as an important source of traditional medicines (e.g. such as herbal medicines) for the people in developing countries as they have little (if any at all) access to any formal health care. This lack of access to medicines and health services is even more acute in the remote and normally more poverty stricken areas of the developing world. It is estimated that approximately 75% of the world's population depends primarily on traditional medicines gathered from the wild. For example, the 'sweet wormwood' plant produces traditional medicines that are increasingly important in combating drug resistant strains of malaria, particularly in Africa (DFIF 2001). Though traditional medicines may not be as effective as compared to scientifically tested drugs, they do provide a cost effective and accessible option in poverty stricken communities. Ash and Jenkins (2007) make reference to importance of biodiversity as a medicinal source by providing some evidence of the number of wild plant species used as a source for curative and preventive drugs. For example, this number is well over 50,000 wild species Chinese (around 20% of all Chinese flora), over 7,000 wild species in India, and 10% of Indonesia's flora. Though these facts are interesting they do not provide a robust empirical indication of the degree of dependency. For this, we would need an assessment of the lives saved or illness incidents avoided as a result of higher levels of biodiversity and then use appropriate value of statistical life estimates to assess the magnitude of these impacts on human welfare. Such studies are non existent.
5.5 Biodiversity and resilience

The term “resilience” has been used to denote an ecosystem’s ability to maintain its basic functions and controls under disturbances (Baumgartner and Strunz 2009, Holling 1973, Carpenter et al. 2001). Higher degree of resilience is found in ecosystems that exhibit higher degrees of biodiversity (see Swift et al (2004) for review of these studies from an ecological perspective). The economic relevance of ecosystem resilience is obvious, as a system flip may entail huge welfare losses since the continued provision of several key ecosystem services would be at risk of total collapse. For example, a combination of drought, fire and ill-adapted livestock grazing management in sub-Saharan Africa, central Asia and Australia have lead to severe degradation and desertification of semi-arid rangelands that provide subsistence livelihoods for more than one billion people. Once these grasslands are degraded they can no longer be used as pasture (Baumgartner and Strunz, 2009). Hence, resilience is related to the threat of ‘irreversible’ ecosystem damage.

There is a growing literature that discusses the value of resilience as insurance against irreversible damage. These papers do make specific reference to this value in relation to the world’s poor. Yet, the discussion is mainly conceptual and model based (e.g. Baumgartner and Strunz 2009; Baumgartner and Quaas 2008a and 2008b, Maler 2008; Perrings 2006; Perrings and Stern 2000). There are no empirical studies on the degree of dependency on biodiversity as a source of protecting from the risk of eroding resilience. This is to be expected given resilience is associated with a form of ‘wider insurance’ against possibly more than one type of risks. It is also a concept related to ‘entire systems’ and not specific aspects of biodiversity and as such is not easy to isolate nor trace back to specific behavioural decisions.

6. CONCLUSIONS

This review paper has examined the published literature which examines links between biodiversity and poverty. Interestingly, while many papers refer to the existence of such a relationship, there are relatively few studies that subject this relationship to critical empirical scrutiny. One (surprising) finding of our review is that there is such a paucity of grounded empirical information about the particular ways in which people (especially the poor) use and benefit from the existence of biological diversity. However, the studies that do exist point to some interesting patterns which are worthy of generalisation. Indeed, it is not necessarily clear that adding to our stock of case study material would necessarily result in the discovery of a hitherto-unknown dimension of the poverty-biodiversity nexus; many of the current known patterns are likely to be repeated in additional studies. More case studies may add some empirical depth, but are not necessarily going to result in a different conceptualisation of the ways in which poverty and biodiversity are related. The limited use of the poverty concept in the existing literature was a further source of disappointment. Here, there are significant missed opportunities, and a more expanded notion of poverty is likely to result in much greater analytical traction for an understanding of the biodiversity-poverty link.
On income and subsistence, our review suggests that there is some evidence supporting the hypothesis that the poor do depend significantly on biodiversity, but this needs to be looked at with some caution. In some cases, there is clear evidence that the use that the poor make of their natural resources as long as these remain relatively low-value and subsistence oriented, but either lose access or are actively excluded from more highly valued resource uses. This suggests that there is some evidence of a possible ‘poverty trap’, with users stuck in low value extractive uses but unable to make the transition out of this resource dependent mode. On the other hand, there is robust information to show that the poor rely on farm agro-biodiversity to insure against food (in)security and risk. However, we still know very little empirically about the economic significance of other forms of biodiversity as risk insurance, biodiversity and resilience; biodiversity and health; and biodiversity and natural hazards. This is an important knowledge gap, and there is a need for more systematic and robust studies which examine these linkages in greater depth.
